

DETECTOR CONFIGURATIONS FOR OPTICAL METROLOGY

Inventor: Jon Opsal

5 **PRIORITY:**

This application is a continuation of U.S. Serial No. 10/137,606, filed May 2, 2002, which claimed priority to Provisional Application Serial number 60/315,514, filed August 28, 2001, the disclosure of which is incorporated herein by reference.

10 **BACKGROUND OF THE INVENTION**

There is ongoing interest in expanding and improving the measurement of semiconductor wafers. A number of optical metrology tools have been developed for non-destructively evaluating the characteristics of thin films formed on semiconductors during the fabrication process. More recently, optical metrology systems have been proposed for
15 analyzing the geometry of small periodic structures (critical dimensions) on semiconductors.

Typical optical tools include reflectometry (both single wavelength and spectroscopic) and ellipsometry (again, both single wavelength and spectroscopic.) In some metrology tools, these various techniques are combined. See for example U.S. Patent Nos. 6,278,519 and 5,608,526, the disclosures of which are incorporated herein by reference.

20 Other metrology tools have been developed which rely on measurements at multiple angles of incidence (both single wavelength and spectroscopic). One class of such systems have been commercialized by the Assignee herein are capable of deriving information about multiple angles of incidence simultaneously. In these systems, a strong lens (high numerical aperture) is used to focus a probe beam of light onto the sample in a manner to create a
25 spread of angles of incidence. An array detector is used to measure the reflected rays of the probe beam as a function of the position within the probe beam. The position of the rays within the probe beam corresponds to specific angles of incidence on the sample. Theses systems are disclosed in U.S. Patent Nos. 4,99,014 and 5,042, 951, incorporated herein by reference. Patent 4,99,014 related to reflectometry while Patent 5,042, 951 relates to
30 ellipsometry. (See also, U.S. Patent No. 5,166,752, also incorporated herein by reference).

In a variant on this system, U.S. Patent No. 5,181,080 (incorporated by reference), discloses a system in which a quad-cell detector (Figure 1) is used to measure the reflected

probe beam. Each quadrant 1-4 of the detector measures an integration of all of the angles of incidence falling on the sample. By subtracting the sums of opposite quadrants, ellipsometric information can be obtained. As described in the latter patent, the information derived from the analysis corresponds to the ellipsometric parameter δ which is very sensitive to the thickness of very thin films on a sample.

The concepts of the latter patents were expanded to provide spectroscopic measurements as described in U.S. Patent No. 5,412,473, also incorporated herein by reference. In this patent, the system was modified to include a white light source. In one approach, a color filter wheel was used to sequentially obtain multiple wavelength information. In another approach, a filter in the form of a rectangular aperture was used to select a portion of the reflected beam. This portion was then angularly dispersed onto an array with each row providing different wavelength information and each column containing the various angle of incidence information.

U.S. Patent No. 5,569,411, also incorporated by reference, disclosed a preferred approach for obtaining spectroscopic information for an integrated multiple angle of incidence system of the type described in Patent No. 5,181,080 discussed above. In this approach, a filter was provided that transmitted light along one axis and blocked light along an orthogonal axis. The transmitted light was angularly dispersed and measured to provide spectroscopic information along one axis of the probe beam. The filter was then rotated by ninety degrees to obtain measurements along the remaining axis. Various modifications of this approach were discussed, including splitting the beam and using two identical filters disposed orthogonal to each other to obtain both measurements simultaneously. (See also "Characterization of titanium nitride (TiN) films on various substrates using spectrophotometry, beam profile reflectometry, beam profile ellipsometry and spectroscopic beam profile ellipsometry," Leng, et. al., Thin Solid Films, Volume 313-314, 1998, pages 309 to 313.)

The integrated multiple angle ellipsometric measurement system described in U.S. Patent No. 5,181,080, cited above has been successfully commercialized and is incorporated into the Opti-Product sold by the Assignee herein. The technology is marketed under the trademark Beam Profile Ellipsometry. (See U.S. Patent No. 6,278,519 cited above.) As described in the '080 patent, the four segments of the quad cell detector can be summed to

provide information about the total reflected power of the probe beam. In addition, the sum of the output of the quadrants along one axis can be subtracted from the sum of the outputs of the remaining two quadrants to provide a result which corresponds to the ellipsometric parameter δ .

5 This arrangement provides valuable information that can be used to determine the thickness of thin films. However, the limited information from this type of detection cannot typically be used to derive both of the ellipsometric parameters, Ψ and δ . U.S. Patent No. 5,586,411, discloses that it would be possible to derive such information if one of polarizers were rotated and multiple measurements taken. As noted therein at column 12,
10 line 48, if enough measurements are taken, a Fourier analysis can be performed on the data allowing the parameters of Ψ and δ to be extracted.

 When designing commercial inspection systems, it is often desirable to minimize the number of moving parts. For example, moving parts often create particulates that can contaminate the wafer. To the extent parts must be moved, the motion systems must have
15 high precision. Further, movements of parts that are specifically designed to modify optical properties, such as retarders or polarizers can effect how the system transmits and detects light.

 Therefore, it is an object of the present invention to enhance the operation of an integrated, simultaneous multiple angle ellipsometric system without the drawbacks of the
20 prior approaches. In particular, the subject invention is intended to permit the derivation of additional ellipsometric information, including both δ and Ψ . In one class of embodiments, this additional information is derived in a system with an improved detector arrangement without the need for moving parts. In another class of embodiments, the rotating element is limited to the detector which does not effect the polarization or retardation of the light.

25

SUMMARY OF THE INVENTION

 In a first embodiment, a narrowband light source such as a laser is used to generate a probe beam. The polarized beam is focused onto the sample in a manner to create a large spread of angles of incidence. The probe beam light is passed through a quarter waveplate
30 for retarding the phase of one of the polarization states of the beam with respect to the other

polarization state of the beam. A polarizer is provided for creating interference between the two polarization states in the reflected probe beam.

In accordance with the subject invention, a detector is provided with eight segments radially arranged around a center axis. In one embodiment, eight pie shaped sections are provided in a configuration which is essentially a quad cell with each quadrant further
5 divided in half. In another embodiment, the eight segments are arranged in an annular ring.

In either case, the output of the segments lying substantially along one radial axis is subtracted from the output of the segments lying substantially along an orthogonal radial axis. In order to gain additional information, the output of the sectors lying along a third
10 radial axis located midway between the first two orthogonal axes (i.e. at 45 degrees) is subtracted from the sectors lying along a fourth radial axis, perpendicular to the third axis. This extra information obtained corresponds to an orientation essentially shifted by 45 degrees from the first measurements. When all the measurements are combined, the sample may be more accurately evaluated. This extra information can be supplied to conventional
15 fitting algorithms to evaluate characteristics including thin film thickness, index of refraction and extinction coefficient. In addition, geometrical parameters of structures formed on semiconductors such as line width, spacing, and side wall angle and shape can also be evaluated. These calculations can be made using the measurements directly. Alternatively, the measurements can be used to derive the ellipsometric parameters Ψ and Δ which are then
20 used to evaluate the sample.

The use of an eight segment detector allows the extra measurement to be obtained simply by summing and subtracting outputs of the sectors in the processor. Other arrangements can be used to provide equivalent results. For example, the reflected beam could be split into two parts and the two quadrant detectors use, one offset by 45 degrees
25 from the other. Alternatively, a single rotatable quadrant detector could be used. After the first measurement is made, the detector could be rotated by 45 degrees and a second measurement could be made. In a preferred embodiment, the output of all the segments is summed to provide a measure of the full power of the reflected beam.

It may also be possible to rotate the either the polarizer or the retarder to achieve a
30 similar result.

The concept can also be extended to the use of a two dimensional detector array. Using a processor, the elements on the array can be computationally mapped to the eight segment and the analysis can be made as described above. This approach can be particularly useful for measurement of critical dimensions, where the orientation of the sample structure and orientation of the probing radiation is significant and possibly difficult to control.

The subject invention can also be extended to spectroscopic measurements. In this case, a white light source would typically be used to generate a polychromatic probe beam. The probe beam could be passed through a color filter or monochromator which sequentially transmits narrow bands of wavelengths. The filter or monochromator would preferably be located before the sample.

If simultaneous multiple wavelength information is desired, it is believed that the approach described in U.S. Patent No. 5,596,411, which included a rotating quadrant filter, grating and array detector would be more suitable than the approach described herein.

Further objects of the subject invention can be understood with reference to the following detailed description, taken in conjunction with the drawings in which:

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a schematic diagram of a quad-cell detector used in prior art measurements.

Figure 2 is a schematic diagram of the optical lay-out of an apparatus for performing the method of the subject invention.

Figure 3 is a schematic diagram of an eight segment detector for use with the subject invention.

Figure 4 is a schematic diagram of a detector having eight detector arms aligned along four axes which can be used to implement the subject invention.

Figure 5 is a schematic diagram of a detector having segments in the form of an annular ring which can be used to implement the subject invention.

Figures 6A and 6B are schematic diagrams of a two dimensional detector array which can be used to implement the subject invention.

Figures 7A and 7B are a schematic diagrams of a rotatable quadrant detector which can be used to implement the subject invention.

Figure 8 is a schematic diagram of a pair of quadrant detectors which can be used to implement the subject invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

5 Turning to FIG. 2, an apparatus 10 is illustrated for performing the method of the subject invention. The apparatus lay out for this embodiment is essentially the same as that described in U.S. Patent No. 5,181,080, except that the detector is configured with eight segments (Figure 3) rather than four segments as in the prior art (Figure 2) . The apparatus is designed to evaluate characteristics at the surface of a sample 14, such as thin film layers 12
10 and/or structural features such as critical dimensions.

 In this embodiment, apparatus 10 includes a light source 20 for generating a probe beam 22 of radiation. One suitable light source is a solid state laser diode which emits a linearly polarized beam having a stable, known and relatively narrow bandwidth. Probe beam 22 is turned towards the sample 14 with a 50/50 beam splitter 44. The probe beam is
15 focused onto the surface of the sample with a lens 26. In the preferred embodiment, lens 26 is defined by a spherical, microscope objective with a high numerical aperture on the order of 0.90 NA. The high numerical aperture functions to create a large spread of angles of incidence with respect to the sample surface. The spot size is on the order of twenty microns or less and is preferably five microns or less in diameter.

20 In should be noted that in this illustrated embodiment, the beam is directed substantially normal to the surface of the sample prior to being focused by lens 26. This configuration helps minimize the spot size on the sample. It is within the scope of the subject invention to direct the beam at a non-normal angle of incidence to the sample as shown in U.S. Patent No. 5,166,752. Although using an off-axis beam increases the spot size on the
25 sample, high angles of incidence can be created with a lower numerical aperture lens.

 Turning back to Figure 1, a fraction of the probe beam power also passes through splitter 24 and falls on an incident power detector 30. As is well known to those skilled in the art, incident power detector 30 is provided to monitor fluctuations in the output power of the probe beam light source. As discussed in U.S. Patent 5,181,080, the incident power
30 detector can be modified to minimize measurement errors which arise due to asymmetries of the beam.

Light reflected from the surface of the sample passes up through splitter 24 towards photodetector 40. Prior to reaching detector 40, the beam 22 is passed through a quarter-wave plate 42 for retarding the phase of one of the polarization states of the beam by 90 degrees. It should be noted that the quarter-wave plate could be located in the beam path
5 prior to the probe beam striking the sample so that the system would operate with circularly polarized light. The latter approach might have some advantages in reducing the aberrations created by lens 26. In addition, while a phase retardation of 90 degrees will maximize the desired signal, other intermediate levels of retardation would be possible.

The beam is then passed through a linear polarizer 44 which functions to cause the
10 two polarization states of the beam to interfere with each other. In order to maximize the desired signal, the axis of the polarizer should be oriented at an angle of 45 degrees with respect to the fast and slow axes of the quarter-wave plate 42.

In accordance with the subject invention, detector 40 is configured to generate independent signals from regions along two pairs of mutually orthogonal axes. In this first
15 embodiment, this goal is achieved by using a photodetector having eight pie shaped segments. As illustrated in FIG. 3, the detector surface includes eight, radially disposed segments 1-8. Each segment will generate an output signal proportional to the magnitude of the power of probe beam striking that quadrant. This signal represents an integration of the intensities of all the rays having different angles of incidence with respect to the sample
20 surface. While this integration approach results in the loss of some information content as compared to an analysis of individual rays, the composite approach does provide significantly greater sensitivity through enhanced signal to noise performance.

The probe beam 22 should be centered on the detector 40 so that each segment intercepts an equal portion of the probe beam. The probe beam should underfill the
25 detector.

The output of the segments is supplied to the processor 50 for evaluation. As in the prior art, the outputs of all the segments can be summed to provide a measure of the full power of the reflected beam. As discussed below, this full power measurement can be used as an input to a regression analysis to determine the characteristics of the sample.

30 In accordance with the invention herein, the processor can also generate measurements which allow additional ellipsometric information to be derived as compared to

the prior art approach. This difference can best be understood by comparing the two approaches.

In general, one measures the total reflectivity of the sample in accordance with the following equation:

5

$$R = \frac{1}{2} (|r_p|^2 + |r_s|^2)$$

The sine of the ellipsometric phase shift δ is determined by the equation:

10

$$\tan \psi e^{i\delta} = |r_p / r_s| e^{i\delta}$$

With the prior art detector of Figure 1, the information is derived as follows:

15

$$\Sigma = 1+2+3+4$$

$$\Delta = (1+3) - (2+4)$$

$$R = \Sigma / \Sigma_0 \text{ and } \sin \delta = \pi/2 (\Delta / |r_p r_s|)$$

20

where Σ_0 is the measured sum signal from a known reference material.

The complete determination of the polarization state requires a measurement that gives $\tan \psi$ and that requires an additional modification to the detector as shown in Figure 3. As noted above, the sum is formed from the outputs of the eight segments as follows:

25

$$\Sigma = 1+2+3+4+5+6+7+8$$

Then as previously:

$$R = \Sigma / \Sigma_0 \text{ and with}$$

30

$$\Delta_1 \equiv (1+2+5+6) - (3+4+7+8)$$

$$\Delta_2 \equiv (2+3+6+7) - (4+5+8+1)$$

35

one has

$$\Delta_1 / \Sigma = 4/\pi (\tan \psi / \tan^2 \psi + 1) \sin \delta \text{ and}$$

$$\Delta_2 / \Sigma = -2/\pi (\tan^2 \psi - 1 / \tan^2 \psi + 1)$$

40

As can be seen, the information from the eight segments can be used to derive both Ψ and δ . In practice, those quantities may not be needed. In fact, it is often preferable to use the measurements more directly in the evaluation of sample parameters. Thus, the invention should not be considered limited to determining both Ψ and δ , but rather is an approach which provides an additional measurement for analyzing the sample.

Although the measurements made by the subject apparatus could be used by themselves to characterize a sample, those measurements can also be combined with other measurement obtained from additional optical metrology devices in manner discussed in U.S. Patent No. 6,278,519. A system with multiple inspection technologies generates a number of independent measurements which are then combined in a regression analysis to determine sample parameters.

Combining data from multiple devices is a procedure quite well known and need not be described in detail. In brief, a mathematical model is defined which describes the structure under test. A best guess of sample parameters is assigned to the model and the optical response is calculated. The calculated optical response is compared to the measured optical response. Any deviations between the calculated optical response and the measured optical response are used to vary the initial starting parameter guesses and the process is repeated in an iterative fashion until satisfactory convergence is reached. (See, for example, the Leng, article cited above.) As noted above, with such an analytical approach it is not necessary to actually calculate Ψ and δ . Rather the inputs from Δ_1 and Δ_2 calculations as set forth above (as well as the full power measurement) are used as inputs actual measurements to the fitting algorithm. Of course, if desired, the Δ_1 and Δ_2 calculations can also be used to calculate Ψ and δ if desired.

These types of analyses are suitable for both thin films and physical structures formed on the sample. It is also possible to use a database or library type approach where a set of the optical responses of a parameterized sample are calculated in advance and stored. The measured response is compared to the stored responses to determine sample parameters. (See, for example, US Published Applications 2002/0038186 and 2002/0035455). The subject invention is not intended to be limited either by the type of sample being measured, nor the specific algorithms used to analyze the data.

As will be discussed below, there are a number of alternative detector configuration which can be used to generate the information of interest. One common thread is that measurements are taken along a first pair of orthogonal axes and along a second pair of orthogonal axes, with the second pair being perpendicular to the first pair.

5 Figure 4 illustrates an alternative configuration for such a detector 440 that satisfies these criteria. Each segment 1-8 is a linear detector arranged in a star-shaped configuration that corresponds to the pie shaped segments of Figure 3. The analysis of the measurements discussed above with respect to Figure 3 would be identical to that of Figure 4.

10 Those skilled in the art will also appreciate that segments 5 to 8 for either the Figure 3 or Figure 4 embodiment are complimentary to segments 1 to 4 so that a detector with only segments 1 to 4 might be used. However, adding the outputs of segments 5 to 8 to the outputs of segments 1 to 4, respectively, makes the detector insensitive to small shifts in the probe beam spot positioning and is therefore the preferred approach.

15 The detector configurations of Figures 3 and 4 will produce a measurement that represents an average over all the incident angles. To examine a narrower range of angles of incidence, a detector 540 as shown in Figure 5 with eight segments arranged in an annulus might be used. Such a detector might be of interest where the probe beam is directed substantially normal to the sample before focusing as shown in Figure 2. In such a case, the radially outermost rays of the probe beam have the highest angles of incidence. The annular
20 ring configuration of Figure 5 would capture only those higher angle of incidence rays, which, in the case of isotropic samples, often carry the most information.

25 The subject invention could also be implemented using a detector 640 comprised of a two dimensional array of detector elements or pixels as shown in Figure 6A. Such a detector could be defined by a CCD array. The pixels in the array could be mapped into eight segments to correspond to the detectors shown in Figures 3 to 5. The mapping of pixels to the detector segments of Figure 3 is shown in Figure 6B. The processor would select the output from the appropriate pixels to calculate Δ_1 and Δ_2 and derive the ellipsometric information.

30 With a sufficiently dense array almost any configuration of angles of incidence is possible. This is especially significant for measuring physical structures (CD) where the xy orientation of the sample structure and the orientation of probing radiation is relevant and

significant. With a system such as described above it is possible (with minimal moving mechanisms) to probe the CD structure from all angles of incidence, planes of incidence and polarizations relative to the orientation of the CD structure.

If it is desired to extend this concept to measure multiple wavelengths, the laser light source 20 could be a white light source that would generate a polychromatic probe beam. A wavelength selective filter 60 (shown in phantom line in Figure 1) would then be placed somewhere in the light path between the light source and the detector. The filter could take the form of simple band pass (color) filters which are selectively moved into the path of the beam. Alternatively, a monochromator could be used to sequentially select narrow wavelength regions. Of course a tunable laser or multiple lasers with different wavelengths could also be used.

Figures 7 and 8 illustrate two further embodiments wherein detectors with only four quadrants can be used to obtain the measurements required herein. Figure 7a illustrates a quadrant detector 740 positioned to take a first set of measurements. Segment 1 would generate an output equivalent to segments 1 and 2 of the detector of Figure 3. Similarly, segment 2 of the detector of Figure 7a would generate an output equivalent to segments 3 and 4 of the detector of Figure 3, segment 3 of the detector of Figure 7a would generate an output equivalent to segments 5 and 6 of the detector of Figure 3 and segment 4 of the detector of Figure 7a would generate an output equivalent to segments 7 and 8 of the detector of Figure 3. This measurement would permit the calculation of Δ_1 .

Once this measurement is made, the quadrant detector could be rotated 45 degrees to a position shown in Figure 7b. In this orientation, segment 1 of the detector of Figure 7b would generate an output equivalent to segments 2 and 3 of the detector of Figure 3. Similarly, segment 2 of the detector of Figure 7b would generate an output equivalent to segments 4 and 5 of the detector of Figure 3, segment 3 of the detector of Figure 7b would generate an output equivalent to segments 6 and 7 of the detector of Figure 3 and segment 4 of the detector of Figure 7b would generate an output equivalent to segments 8 and 1 of the detector of Figure 3. This measurement would permit a calculation of Δ_2 .

The detector configuration of Figure 7 might be desirable to simplify and minimize the cost of the detector. However, the trade off would be that the measurement would require two steps and the rotation of an element. Rather than rotating the detector, similar results

might be achieved if either the polarizer or analyzer or both were rotated to provide independent measurements.

Figure 8 illustrates a configuration conceptually similar to Figure 7 but which would allow both measurements to be taken at once. More specifically, after the probe beam is reflected from the sample and passes the polarizer and waveplate, it can be divided by beam splitter 802. Two separate quadrant detectors 840 and 842 are each located in one of the two beam paths. The quadrants of detector 840 are offset from the quadrants of detector 842 by 45 degrees. The output of the quadrants of detector 840 can be used calculate Δ_1 and the output of the quadrants of detector 842 can be used to calculate Δ_2 . As an alternative, one could place the beam splitter in the path of the reflected probe but before the quarter waveplate and polarizer. In this alternative, it would be necessary to place a quarter waveplate and a polarizer in each path. In this arrangement, it would also be possible to orient both detectors at the same azimuthal angle, but have different positions for either the waveplate or the polarizer in one path as compared to the other path.

While the subject invention has been described with reference to a preferred embodiment, various changes and modifications could be made therein, by one skilled in the art, without varying from the scope and spirit of the subject invention as defined by the appended claims.
